Abstract
Despite its long use in clinical settings, the checkered reputation of hypnosis has dimmed its promise as a research instrument. Whereas cognitive neuroscience has scantily fostered hypnosis as a manipulation, neuroimaging techniques open new opportunities to use hypnosis and posthypnotic suggestion as probes into brain mechanisms, and reciprocally, provide a means of studying hypnosis itself. We outline how the hypnotic state can serve as a way to tap neurocognitive questions and how cognitive assays can in turn shed new light on the neural bases of hypnosis. This crosstalk should enhance both research and clinical applications.

Résumé
Malgré sa longue tradition clinique, la réputation contrastée de l'hypnose a faiblit comme instrument de recherche. Si la neuroscience cognitive a peu fait progresser l'hypnose comme procédure, les techniques d'imagerie cérébrale offrent de nouvelles opportunités d'utiliser hypnose et suggestion posthypnotique comme sondes des mécanismes cérébraux et réciproquement fournir un moyen d'étudier l'hypnose elle-même. Nous exposons comment l'état hypnotique peut servir de biais pour approcher les questions neurocognitives et comment les analyse cognitives en retour peuvent jeter un éclairage sur les bases neurales de l'hypnose. Ce dialogue croisé devrait stimuler la recherche et les applications cliniques.

Zusammenfassung
Trotz ihrer langen klinischen Tradition, hat der bewährte Ruf der Hypnose als Forschungsinstrument abgenommen. Während die klinische Neurowissenschaft die Hypnose als Verfahren nicht unbedingt weiter brachte, bieten die Techniken der Gehirnbilder neue Möglichkeiten, die Hypnose und die posthypnotische Suggestion als Sonde der Gehirnfunktionen zu verwenden und liefern wechselseitig ein Mittel, die Hypnose selbst zu verstehen. Wir legen dar, wie der hypnotische Zustand als Weg dazu dient, die neurokognitiven Fragen zu erforschen. Anschließend können die kognitiven Analysen einen Beitrag bezüglich der neuronalen Grundlagen der Hypnose leisten. Dieser wechselseitige Dialog sollte die Forschung und die klinischen Anwendungsmöglichkeiten stimulieren.
Hypnosis has been used clinically for hundreds of years and is primarily a phenomenon involving attentive receptive concentration. Historically, hypnosis was defined as an altered state of consciousness, characterized by heightened compliance with suggestion and extreme focused attention. Whereas this definition presumes a specific theoretical view, over the years this characterization of hypnosis was gradually refined and amended to reflect a more theoretically neutral approach. Nonetheless, one persistent barrier to the scientific use of hypnosis has been the idea that it involves a special and mysterious state of consciousness, often referred to as trance. Although trance phenomena have been long used in initiation rites and other ceremonies in many cultures, research inspired by this approach has not supported the trance hypothesis. Moreover, the idea of trance has impeded serious consideration by investigators. However, that the rejection of the concept of trance in no way impugns the reality of subjects' responses evoked by hypnotic inductions and suggestions. These procedures generate changes in the way in which people experience themselves and the environment, and these alterations have been shown to affect cognitive processing.

Hypnosis and hypnotherapy must be distinguished. Hypnotherapy conveys the misimpression that hypnosis is a type of therapy, perhaps because it is a treatment modality in which the patient is in the hypnotic state at least part of the time. However, there is widespread accord that hypnosis, in itself, is not a treatment but rather an adjunct to therapy. Whereas a patient who achieves the hypnotic state may experience reduced tension and other benefits, further goal-related interventions, such as suggestions about pain relief or cessation of smoking, are necessary to make it hypnotherapy.

Hypnosis has largely remained an elusive concept for science, because it is contaminated by folk beliefs and shrouded in layers of misconception. Recently investigative techniques have done little to demystify hypnotic phenomena. In this brief overview we present an agenda for research based on modern neuroscience applications and recent data to delineate how hypnosis and cognitive neuroscience can be wed into a successful relationship. Imaging techniques of the living brain may illuminate the anatomical and functional nature of hypnosis. Moreover, hypnosis can also be used as a tool to study cognitive phenomena, as we unravel some of the neural mechanisms subserving hypnotic expression.

History

Hypnosis was notably driven into the realm of the mysterious by Franz Anton Mesmer's 18th century theory held that all objects in the universe were connected by and filled with a fluid-like substance possessing magnetic properties. Mesmer used eye gaze accompanied by dramatic hand gestures, to apply his own "magnetic influence" to restore his patients' magnetic fluid to proper balance. Although the French-appointed Benjamin Franklin Commission blamed Mesmer's animal magnetism theory in 1784, contention between his doctrinaire and skeptics persisted.

Within the medical establishment, Jean-Martin Charcot and then his student Pierre
Janet believed that hypnosis was related to hysteria and described various stages of the phenomenon in relation to a concept of pathology. A critical point in the history of hypnosis came in 1880, when Josef Breuer and young Freud treated a «hysterical» patient in self-induced hypnoid trances. The treatment was effective and both men later wrote Studies in Hysteria. Freud subsequently gave up hypnosis and continued the relaxation focus through free association. Currently, 121 years later, data emanating from single-patient case studies using brain imaging suggest that hypnosis and hysteria indeed may share common neurophysiological mechanisms involving prefrontal regions.\textsuperscript{10,11,12} Albeit this evidential base is meager, the common anatomy suggests that treating symptoms of conversion hysteria may be illuminated by hypnosis.

Common false theories continue to associate hypnosis with mysticism, loss of autonomy, and mind control. As popularly depicted in cartoons and films, many incorrectly believe that hypnosis is a variant of sleep, permitting a loss of will and submission to the hypnotic coach. The term hypnosis is a misnomer, associating the phenomenon with sleep (and death). Hypnos, who in Greek mythology is the God of sleep and dream (and brother of Thanatos, god of death), was misleadingly chosen as the designator of this state. Whereas exaggerated claims and blatant displays by lay and stage hypnotists continue to captivate the public, approximately 150 articles on hypnosis annually appear in mainstream medical and scientific journals.\textsuperscript{13} Moreover, the American Medical Association, Chicago, Ill., and other medical associations, formally recognize hypnosis as a valid adjunct for medical treatment.

Although some countries (e.g., Israel) require hypnotists to be formally trained and licensed by a supervising board, many countries (e.g., the United States) pose no such legal demands. The professional using hypnosis is a «hypnotic operator»\textsuperscript{14} who determines the subject’s hypnotic capacity, and then teaches the subject to achieve the meditative state, and, if the subject is willing, stimulates his or her imagination.

One of the most interesting feats of hypnosis is the observed alteration in volitional control over behavior. Individuals who are highly hypnotizable may either perform movements that they report as having occurred without volitional control or be unable to execute simple motor acts in response to challenge suggestions. Historically, such phenomena were taken at face value, supposing that hypnotic behavior was unintentional. In later years, however, the volitional status of suggested behavior has become a source of passionate argument.\textsuperscript{15}

Therapists may well be practicing hypnosis (or hypnosis-like work) when they engage children and adults, alike, in conversation during which participants appear absorbed or seem to be paying close attention.\textsuperscript{16} Indeed, hypnosis is sometimes indistinguishable from the simple physical or mental repose of focused attention encountered in daily activities. For example, sports figures describe «being in the zone» when they achieve their best-focused performances. In fact, there is a kinship between hypnosis and attentive play, prayer, study, or rumination. The striking similarity between relaxation training, meditation, and typical hypnotic induction is easily recognized. Yet, hypnosis is not identical to imagery and relaxation training, because suggestion need not entail
requests for imagery and, albeit not common, hypnosis can be induced without relaxation.\textsuperscript{17,18}

**Measuring Hypnosis-like States**

The introduction of imaging techniques of the living brain has opened new avenues to study hypnosis. A few studies have explored the role of imagination in cognition\textsuperscript{19} and imaged brain activity under meditation\textsuperscript{20,21} concluding that characteristic patterns of neural activity support this state. A comparison of the resting state of normal consciousness with meditation in a positron emission tomography study\textsuperscript{22} showed differential activity mainly in prefrontal structures (e.g., the dorso-lateral, orbito-frontal, and anterior cingulate gyrus), but also in other areas thought to be involved in executive attention (e.g., the left parietal and inferior parietal lobule, striatal and thalamic regions, and cerebellar hemispheres and vermis).

Although based on scanty references\textsuperscript{23,24}, clinicians practicing hypnosis suggest that, when one is in a hypnotic state, attentional and perceptual changes may occur that would not have occurred had one been in a more usual state of awareness. Hypnotic perceptual alteration in a responsive subject is usually accompanied by changes in brain activation.\textsuperscript{25,26} Recent data\textsuperscript{27,28} support the claim that the state of hypnosis is associated with distinct neural correlates, and therefore is more than role-playing\textsuperscript{29} or social compliance.\textsuperscript{30} One study showed that whereas activity in the right anterior cingulate cortex was comparable when subjects were either hallucinating or actually hearing auditory stimuli, a marked decrease in anterior cin-
gulate activity followed when subjects were imagining that they heard the sounds. Another study showed that hypnosis affected low-level brain processes such as color perception. Subjects under hypnosis were able to see color in black and white photos, and perceive only shades of gray when looking at a color image on suggestion. Variations in the subjective experience of these highly responsive subjects under hypnosis were associated with positron emission tomography measurements of changes in brain function typical of veridical perceptual alterations.

Several standardized measures, with good psychometric characteristics, are available to reliably assess hypnotizability. For example, the Stanford Hypnotic Susceptibility Scales,\textsuperscript{31,32} two variations of which have been developed for use with children and adolescents,\textsuperscript{33} have excellent test-retest reliability after long intervals. Although such terms as hypnotic susceptibility, responsivity, suggestibility, and depth actually embrace some subtle nuances, they are typically used interchangeably to indicate the quantifiable rating of a subject's response to hypnotic suggestions under standard conditions. It is common to classify people as either low or highly hypnotizables, depending on their performance on a particular scale. However, some researchers have attempted to change hypnotic susceptibility by using programs that enhance hypnotic suggestibility.\textsuperscript{34} These techniques, which often include elements of self-deception, are usually used in order to make hypnotherapy available to a wider group of clients in clinical settings.\textsuperscript{35}

Post-hypnotic suggestion refers to a condition following termination of the hypnotic experience, where a subject is
compliant to a suggestion made during the hypnotic episode (e.g., to change chairs, rise and stretch or forget a fact), but does not remember being told to do so. The post-hypnotic suggestion is usually summoned on a prearranged signal and can be effective in highly responsive individuals.

Hilgard\cite{hilgard1959} compared some of the better-known scales for hypnotizability that had been described in the literature during the 19th and 20th centuries. Of the modern measures available, the Stanford Hypnotic Susceptibility Scale Form C stands out, because it includes items that more fully assess the subject's ability to experience hypnotic distortions of perception and memory and allows for a finer discrimination of hypnotizability. The Stanford scales, which typically require about 75 minutes to administer, have been effective because of their superior psychometric characteristics. Whereas these scales were primarily designed for academic research, permitting a decision regarding experimental participation, clinical constraints (e.g., time, population, posture) have forced most practitioners to profile patients using briefer clinical scales (e.g., the Stanford Hypnotic Clinical Scale (SHCS), Stanford Profile Scales of Hypnotic Ability (SPS) or the Hypnotic Induction Profile (HIP)\cite{hip,spc,shcs}).

The introduction of functional brain scans offers a new research opportunity to study hypnosis and to use it as an experimental condition measured against a non-hypnotic state. Increasingly sophisticated imaging techniques of the living brain (e.g., functional magnetic resonance, positron emission tomography, optical imaging) have made it possible to observe activation of neural regions when people perform complex cognitive tasks (e.g., involving attention, language or perception, etc.)\cite{fnc,bot} A review of the literature reveals that neuroimaging studies\cite{bot,bot2,bot3,bot4,bot5,bot6,bot7,bot8} have examined hypnotized subjects. These studies usually endeavor to capture a specific hemodynamic pattern underlying the multiple cognitive processes involved in the hypnotic state.

Traditionally, hypnosis was studied as one of the most effective behavioral interventions for acute and chronic pain. Hypnotic analgesia\cite{bot9} is regarded as an active process requiring inhibitory effort, albeit this effort may be dissociated from consciousness.\cite{bot9} Imaging technology has fostered this line of investigation.\cite{bot10,bot11,bot12,bot13,bot14} These studies report significant signal changes in areas associated with sensation and perception (e.g., primary somatosensory cortex, thalamus, and insula) and sensori-motor integration pain systems (e.g., supplementary motor cortex). However, pain-control represents only a narrow area of inquiry considering the panoply treasured by hypnosis.

Although it has been shown that pain and attention activate similar brain areas (e.g., the frontal and anterior cingulate cortices)\cite{bot15,bot16} and that hypnosis is a powerful attentional manipulation,\cite{bot17,bot18,bot19,bot20,bot21} there are too few studies focusing on the effects hypnosis may have on such basic attentional processes as inhibition and facilitation, relative to with current information in the cognitive neuroscience literature. In fact, new positron emission tomography data\cite{bot22} suggest that hypnosis modulates activity in cerebral structures involved in arousal and attention. Blood flow in the brainstem was correlated negatively with relaxation and positively with absorption. This suggests the invocation of thalamo-cortical arousal and attentional networks in the instigation of hypnosis.
Furthermore, congruent with research supporting frontal lobe activity and the role of the neurotransmitter dopamine in attentional processing and hypnosis, a positive correlation between measured hypnotizability and the activity of the dopaminergic system (as measured in cerebrospinal fluid by looking at homovanillic acid, a metabolite of dopamine) was reported. Hence, a programmatic plan that integrates hypnosis into attentional and genetic research seems worthwhile.

Hypnosis and Attentional Network

Since the late 19th century, attention in general and selective visual attention in particular, have been important areas of study. How attention relates to the brain has remained controversial. Modern cognitive assays have suggested that attention is neither a property of a single brain area nor that of the entire brain. Attention can be viewed as involving a system of anatomical areas consisting of at least 3 more specialized networks. These networks carry out the functions of alerting, orienting, and executive control. Whereas the idea of separate locations of attention has often been discussed, only with the aid of neuroimaging— as the field of cognitive neuroscience approaches its 20th birthday— has it been indicated that distinct brain areas mediate different attentional processes.

Pharmacological studies on alert monkeys have related each of the attentional networks with specific chemical neuromodulators. Alerting is thought to involve the cortical distribution of the brain's noradrenergic system arising in the locus coeruleus of the midbrain; cholinergic systems arising in the basal forebrain play an important role in orienting; and the anterior cingulate and lateral frontal cortex are target areas of the ventral tegmental dopamine system. (Figure)

Regrettably, to date most scientists studying the attentional system have not

![Diagram of brain with labels](image)

Figure 1. A sketch of the functional anatomy of the attentional networks. The pulvinar, superior colliculus, superior parietal lobe and frontal eye fields are often activated in studies of the orienting network. The temporoparietal junction is active when a target occurs at a novel location. The anterior cingulate gyrus is an important part of the executive network. Right frontal and parietal areas are active when people maintain the alert state.
used hypnosis as a variable manipulation. This reluctance may be the result of the negative social history associated with this oniric state as well as by the misguided view in classifying it as a clinical technique of only anecdotal research merit. Nonetheless, there are nascent efforts to measure these separate attentional networks.\textsuperscript{70,71} It is intriguing to investigate which attentional networks, if any, can be modulated by hypnosis and post-hypnotic suggestion. Notably, such information will have important clinical and scientific merits, as we begin to segregate and relate the executive, alerting, and orienting components of the attentional system to separate anatomical sites.

Hypnosis, however, could be used to study additional function systems as it offers attractive prospects to many fields of cognitive research (e.g., mental imagery, memory, and perception, etc.). It is a singular non-invasive technique, which can incite a dramatic effect on attentional and cognitive processing via verbal exhortation. Furthermore, highly responsive individuals can be induced in an expeditious, impromptu fashion, without elaborate technical preparation.

Because subjects may vary in the levels of depth during the hypnotic session, post-hypnotic suggestion can also be employed in order to facilitate a «cleaner» experimental manipulation.\textsuperscript{72} For example, as part of the induction of subjects involved in a reading experiment, a specific instruction can be included suggesting that they will only consider the vertical lines of the symbols showing on the screen on each trial. This active blocking instruction may be effective to prevent the subjects from processing words as lexical units with semantic significance. There already is evidence in the literature suggesting that such manipulations can be performed.\textsuperscript{50,73} However, few paradigms take advantage of such potentially important data.

Furthermore, because post-hypnotic suggestion can be triggered and disengaged on a specific cue (e.g., auditory or visual) it is possible to alternately explore effects within a subject in natural as well as manipulated states.

In addition, hypnosis is experimentally appropriate for investigating developmental neurocognition. Pediatric hypnosis and hypnotherapy have been studied scientifically and documented for more than 200 years.\textsuperscript{74,75} Most children are highly hypnotizable, and hypnosis is more easily induced with them than with adults.\textsuperscript{16,76,77} Yet, there is no evidence that hypnosis in children is a different phenomenon from that studied in adults.\textsuperscript{78}

In conclusion, clinicians practicing hypnosis and cognitive neuroscientists could benefit by using their expertise to exploit hypnosis as a probe into the neural bases of cognition. Such an endeavor can only increase our understanding of these phenomena. Too few higher-order manipulations are as experimentally advantageous as hypnosis and post-hypnotic suggestion. Whereas the clinical effectiveness of hypnosis is documented, little has been done to harness this special phenomenon as a means of illuminating cognitive questions, despite its obvious relationship to attention, perception, memory and consciousness in light of recent progress in the field of cognitive neuroscience. Neuroimaging technology renders hypnosis particularly enticing not only as a potent cognitive manipulation but also as effective meditative means to lower tension, alleviate anxiety, and reduce mo-
vement for the duration of imaging
scans. Furthermore, recent neuroimaging data suggest a potential anatomical
(morphological and volumetric) basis for hypnotizability, linking variations in the
rostrum of the corpus callosum to differences in attentional and inhibitory
processing. Hypnosis is also particularly apt for developmental studies, as most children
are highly responsive to hypnotic induction. Further inquiries into the developmen
tal correlates of the phenomenon, as they relate to the stage of cognitive and
social capacities, seem highly promising. Finally, in the aftermath of the Human
Genome Project, where genotyping is increasingly possible, hypnotic responsiv
ness can be studied in the context of behavioral genetics, thereby opening the
way to discover a genetic basis for hypnotizability and associated cognitive capac
ities. On the flip side, new information to be derived from the marriage of these as
says may provide better scientific descriptions of the phenomenological correlates
of hypnosis, and allow us to demystify a chthonic trait of human consciousness.
